### SCHMARY

<sup>101</sup>L-Schistonean nectors is throtogomelum surface actigons were unconseperceptized with human antibodies from including Egyptium patients diagnosed as being either acusely or chronically sufected with S, measure. Both sets of patients were found to have  $1_{\mathbb{C}}S$  antibodies in their sets capable of measure-precipitating the major M, S, measure. Both sets of patients were found to have  $1_{\mathbb{C}}S$  antibodies in their sets capable of measure-precipitating the major M, S, and S1K articipens. However, the immunopercipitation of the M, S and S1K articipens were found to the total precipitate dispersion of the social precipitation that these two antigens constituted was not found to be significantly different between the two sets of sets. Immunopercipitation with pooled antibodies absorbed with egg and adult worm homogenates which had been treated to remove either carbohydrate or palypeptide epitopes demonstrated that the M, S and S1K antigens were found to be precipitated by antibodies to protest-ensistive and percoduce-microstrate played epitopes. These results are consistent with eggenost-resulting antibody among the antigens detected. The M, M and M are found to be precipitated by antibodies to protest-ensistent M1C antibody making a greater contribution to schintosomulum surface recognition in acute infection than in chronic section, Indeed the presence of a higher level of egg-cross-reactive and anti-carbohydrate authody directed against schintosomulum surface reprotopes in an acute serum pool than in a chronic serum pool was confirmed by measurement of antibody binding to whole schistosomulum surface recognition in confirmed by measurement of antibody binding to whole schistosomulum.

Key words: Schittosona massour, schistosomula, antigens, human antisera, carbohydrate epitopes, polypeptide epitopes

## INTRODUCTION

Extensive analysis of Schistosoma mansoni schistosomulum surface recognition by murine IgG has demonstrated two distinct sets of epitopes. More than 90% of such epitopes are sodium metaperiodate sensitive earbohydrate structures which cross-react with the parasite egg. A smaller percentage are noncarbohydrate structures that do not cross-react with the egg (see Kelly (1987) for review). Epitopes of both types have been shown to be the target of protective murine monoclonal antibodies and are thus potential targets of protective immune responses (Omer Ali et al. 1988). Immunoprecipitation experiments have identified schistosomulum surface antigens of M. > 200, 38 and 17K which express egg-cross-reactive carbohydrate epitopes and antigens of M, 38, 32 and 20K which express noncarbohydrate epitopes (Omer Als et al. 1988).

Human antibodies have been shown to immunoprecipitate schistosomulum suiface antigens of similar M, to those recognized by mice (Simpson et al. 1986). Furthermore, antibody has been detected in the sera of Kenyan children infected with S, masson to both earbohy drate and non-carbohy drate epitopes

extracted from schistosomula, although it has not been demonstrated whether these are expressed on the surface (Dunne et al. 1988). Nevertheless, Dunne et al. (1988) found that there was a correlation between the levels of antibody to carbohydrate epitopes extracted from the schistosomulum and the egg and a correlation between antibodies to non-carbohydrate epitopes extracted from the schistosomulum and the adult worm. These observations are consistent with the epitopes being shared between the respective life-cycle stages and suggest that similar surface epitopes may be recognized by human and murine antibodies.

In order to test this possibility the specificaties of anti-schistosomalum surface IgG antibodies in the sera of Egyptian patients infected with S. maniom have been examined. Serum was taken from both acutely and chronically infected individuals. Acute schistosomiasis typically occurs 1-2 months after initial exposure to in-ected water and is diagnosed on the basis of fever, eosinophilia, stool examination and serology (see you Lachtenberg, 1987). Comparison of the immune responses of such patients with those known to have been infected for several years enables early and persistent responses to be differentiated. It was considered that such analysis may be of value in determining responses likely to

contribute to resistance to reinfection which has been shown to develop only after several years of exposure in individuals in endenne communities (Betterworth & Hagan, 1957).

# MATERIALS AND METHODS

#### Paracita

A Puerto Rican strain of S, measure is maintained in humsters and Biomphalaria glabrata at the National Institute for Medical Research and was used throughout the study. Schistosomula were prepared by mechanical transformation of cercariae and incubation for 3 h at 37 °C in Earle's salts plus lactalbumin hydrolysate (Ramalho-Pinto et al. 1974).

### Anticera

All human sera were collected from patients admitted to the FUO ward of the U.S. Naval Medical Research Unit No. 3 in the Abbassia Fever Hospital, Cairo, in 1985–86. All sera were stored at ~20 °C prior to serological analysis. None of the patients had been previously treated for schistosomissis.

Twelve sera were collected from patients who had been diagnosed as suffering from acute schistosomiasis. These patients were all to-in dwellers who were exposed briefly for the first time to infected Nile water. Eggs of S. mansoni were found in all patients, although repeated stool examinations or rectal snip were required to find the eggs in some cases. The patients ranged in age between 5 and 14 years and had fever of 3-8 weeks, duration with diarrhoea, high cosinophilia and palpable tender livers. The length of fever is consistent with all the patients being infected 8-13 weeks prior to serum collection.

Thirteen patients from rural communities had a well-documented active infection of at least 3 years. They were all excreting eggs in their faces and ranged in age between 10 and 24 years. Precise age matching of the two groups of patients was not feasible since acute infection tends to occur in younger patients and patients with documented infection of at least 3 years of the same ages were not available.

Pools of the acute and chronic sera were constructed by mixing equal  $50\,\mu l$  samples of each serum. The serum pools were also stored at  $-20\,^{\circ}\mathrm{C}$ 

Normal sera were obtained from healthy laboratory workers at NAMBU 3, Cairo.

# Antigen detection assays

Measurement of antibody binding to intact and sodium metaperiodate-treated schistosomula was undertaken exactly as described previously (Omer Ali et al. 1986) using <sup>128</sup>1-protein A (Sigma) or <sup>128</sup>1protein G (Perstwep Boolytica) to detect bound antibody. Radio-asotope labelling was undertaken usung Iodogen (Fraker & Speck, 1978), resulting in a specific activity of 1-4x 10° epin/gg.

Schistosomala were surface labelled using Iodogen and <sup>12</sup>I-labelled astigens (I-2x 10° epm) precipitzed with a 1/I0 dilution of antibody and protein-A Sepharose (Pharmacia) (Knight et al. 1981). Electrophoretic analysis was undertaken using 125° a 505° polyacrylamide gels which were subsequently dried and exposed for autoradiography. For quantitative analysis the autoradiography were scanned using a Joyce-Lobel densitoneter and the intensity of individual bands calculated as a percentage of the total precipitation. The significance of the variation of the relative intensity of individual bands between the acute and chronic sera was calculated using Student's 1 test.

# Depletion of sera by absorption with adult worm and egg homogenates

Adult worms and eggs were homogenized in phosphate-buffered saline, pH 74 (PBS) containing 10 mss ethylenediaminetetraacetic acid (EDTA) to give a suspension containing approximately 10 mg/ ml of protein. The homogenates were divided into three parts. The first was digested with 100 µg/ml of proteinase K (the reaction being stopped by the addition of phenylmethylsulphonyl fluoride at a final concentration of 5 m31), and then boiled for 1 h. The second was incubated with 100 mM sodium metaperiodate for 1 h at room temperature and the reaction stopped by the addition of ethylene glycol at a final concentration of 100 may. The third was diluted with PBS to give the same final protein concentration as the treated antigens. The treated antigens were dislysed overnight against PBS at 4°C. For absorption each antigen was incubated overnight at 4 °C with an equal volume of antibody The particulate antigen was then removed by centrifugation at 12000 g for 10 min and the supernatant fraction used for immunoprecipitation

### BESIII TS

Immunoprecipitation of <sup>181</sup>I-schistosomulum surface antigens was undertaken with sera from individuals diagnosed as being acutely or chronically infected with *S. manion*. (Fig. 1A and II) Both sets of sera produced variable precipitation of labelled proteins of  $M_1$  15–20K and 60–100K. The major features of the precipitation profiles, however, were the  $M_s > 200$ , 38 and 32K antigens. The chronic sera consistently exhibited an intense precipitation of both the  $M_s$  38 and 32K antigens, whereas the precipitation of these antigens was more variable amongst the acute sera. Four acute sera preferentially precipitated the  $M_s$  38k antigen and one contained the  $M_s$  38k antigen and one contained

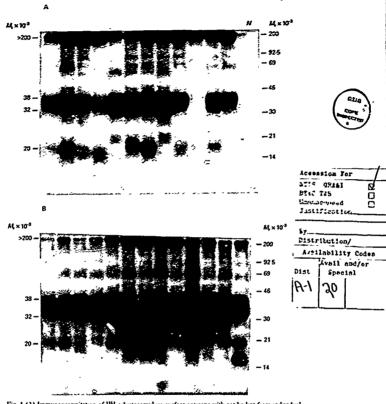

Fig. 1.(A) Immunoprecipitation of <sup>118</sup>I-schistosomulum surface antigens with antibodies from individual patients with seute schistosomasis. N, precipitation with normal human serum (B) Immunoprecipitation of <sup>118</sup>I-schistosomulum surface antigens with antibodies from individual patients with chronic schistosomasis

no detectable IgG antibody against either of these two antigens. All the sera tested contained antibodies against the M<sub>1</sub> > 200K antigen. However, the precipitation of this antigen by the acute sera was relatively more intense. Quantitative analysis of the immunoprecipitations was underasken by scanning the autoradiographs of the gels with a Joyce-Lobel densitometer. The relative intensity of immunoprecipitation of individual bands was calculated as a percentage of the total precipitation in each lane.

This method of quantitation was used to control for possible variations in the amount of antibody or radio-isotope labellec protein in individual precipitations. The percentage of total precipitation constituted by the  $M_s > 200 \mathrm{K}$  and the  $M_s$  38 and 32K antigens combined is shown in Table 1 Comparison of the results by Student's t test demonstrated that precipitation of the  $M_s > 200 \mathrm{K}$  antigens constituted a significantly greater percentage of the total precipitation in the secute sera than in the chronic sera

Table 1 Statistical analysis of the relative levels of immunoprecipitation of the  $M_\star>200{\rm K}$  and  $M_\star$  38/32K schistosomulum surface antigens by antibodies in the sera of patients with acute and chronic schistosomiasis

(The values for the immunoprecipitation of the antigens were calculated by dividing the absorbance corresponding to each antigen band on the autoradiograph shown in Fig 1, by the total absorbance for all bands in the immunoprecipitate)

Patient type	Number	V, > 200K	M, 38/32K		
Acute Chronic	12 13	40-7 ± 21-3 13 4 ± 4 1	42-4 ± 15 8 49-0 ± 5 4		
Significance		t = 452 P < 0001	1=12 P \x		

The M, 38 and 32K antigens, on the other hand, did not constitute a significantly different proportion of the total precipitation in the two groups of patients

The cross-reactivity between life-cycle stares and the contribution of carbohydrate and polypeptide

moieties to the epitopes recognized on the principal schistosomulum surface antigens of  $M_r > 200$ , 38 and 32K were assessed by absorption experiments using serum pools. Absorption of the acute serum pool with a schistosome egg homogenate greatly reduced its ability to precipitate the 1251 surface antigens (Fig. 2A) Pre-treatment of the egg homogenate by boiling and digestion with proteinase K, to destroy polypeptide epitopes, did not affect its ability to absorb anti-M, > 200K antibody but did reduce its ability to absorb anti-M, 38 and 32K antibody Pre-treatment of the homogenate with periodate, on the other hand, prevented the absorption of the anti- $M_{\star} > 200 \text{K}$  antibody but not the anti-M, 38 and 32K antibodies. Thus the anti- $M_{\star} > 200$ K antibody in the acute serum pool is directed against periodate sensitive, protease insensitive epitopes which are shared with the schistosome egg. The anti-M, 38 and 32K antibodies, on the other hand, are directed against periodate insensitive, protease sensitive polypeptide epitopes

Absorption of the chronic serum pool with egg homogenate only resulted in a reduction in the

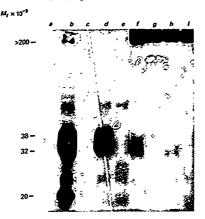

Fig. 3. Immunoprecipitation of <sup>183</sup>I-schistosomulum surface antigens with antibodies from sera pooled from patients with acute and chronic schistosomissis and the effect of absorption with whole adult worm homogenate. a, Normal human serum; b, intact chronic serum (alluted with PIS to control for the dilution that occurs during absorption, see Materials and Methods section); c, chronic serum absorbed with mater homogenate, d, chronic serum absorbed with homogenate digested with proteinase K and boiled, c, chronic serum absorbed with homogenate treated with shodium metasperiodate, f, intact acute serum (diluted with PIS to control for the dilution that occurs during absorption); g, acute serum absorbed with intact homogenate, h, acute serum absorbed with homogenate treated with sodium metaperiodate, which is a control to the dilution that occurs during absorption); g, acute serum absorbed with intact homogenate higested with proteinase K and boiled, r, acute serum absorbed with homogenate treated with sodium metaperiodate.

relatively weak precipitation of the  $M_e > 200 \mathrm{K}$  antibody (Fig. 2B). As with the acute serum pool this absorption was abolished by pre-treatment of the egg homogenate with periodate. The  $\kappa$  was no other reduction of precipitation. This indivated that whereas anti-egg antibody contributed the majority of the anti-sch-istosomulum surface IgG in the acute serum pool it made a negligible contribution to surface recognition in the chronic serum pool

Absorption experiments were also undertaken using an adult worm homogenate (Fig.) Absorption of the chronic serum pool completely abrogated its ability to immunoprecipitate schistosomulum surface antigens. Boiling and protease treatment, but not periodate treatment, presented the absorption of anti-M, 38 and 32K antibody, demonstrating that these were entirely directed at polypeptide epitopes. Absorption of the acute scrum pool with the adult homogenate did not alsorb antibody to the M, > 200K antigen although the precipitation of the M, 38 and 32K was abolished. As in previous experiments absorption of these anti-bodies was prevented by protease but not periodate treatment.

The analysis of surface antigen recognition by

immunoprecipitation of 1251-surface antigens thus demonstrated that the  $M_{\star} > 200 \text{K}$  antigen is the principal target of egg-cross-reactive anti-carbohydrate antibody in the patients examined and that there is a significantly greater proportion of antisurface antibody directed against this antigen in the sera of acute patients than chronic patients. If the epitopes recognized on this antigen are exposed on the schistosomum surface and constitute a significant proportion of the total surface epitopes as they have been shown to do using mouse sera (Omer Ali et al. 1986, 1988), a significant difference in the binding of the serum pools to whole schistosomula would be predicted To test this prediction binding assays to whole schistosomula were undertaken. The binding of the acute serum pool to intact schistosomula was found to be approximately 8-fold higher than that of the chronic pool. This high level of binding of the acute serum pool was reduced by 83% by absorption with egg homogenate (Fig 4) In contrast, no change in the level of binding of the chronic serum pool was detectable. A similar reduction in binding of the acute serum pool resulted from the pretreatment of the schistosomula with sodium metaperiodate which did not after the level of binding

Fig. 4. The binding of antibodies from sera pooled from patients with acute and chronic schistosomiasis to the surface of schistosomiala. Hatched bars represent binding of antibody absorbed with whole egg homogenate. NHS = normal human serum. Each serum pool was used at a 1/10 dilution. Each bar is the average of duplicates.

exhibited by the chronic pool (Fig. 5). In this experiment protein-G, which binds to all human IgG subclasses was used to exclude the possibility of significant levels of anti-carbohydrate IgG, antibody in the sera of the chronic patients which would not be recognized by protein-A.

# DISCUSSION

It has been demonstrated here that antibodies from Egyptian patients both acutely and chronically infected with S, mannow hand to the schistosomulum surface and immunoprecipitate surface antigens. Immunoprecipitation of <sup>119</sup>I-schistosomulum surface antigens with individual sera demonstrated that all those tested contained antibodies against the  $M_{\rm f} > 200{\rm K}$  antigen. However, quantitative analysis of the immunoprecipitations revealed that there was a statistically significant difference in the relative intensity of precipitation of the  $M_{\rm f} > 200{\rm K}$  antigen by antibodies in the acute sera than antibodies in the chronic sera. This indicated that there is more anti- $M_{\rm f} > 200{\rm K}$  antibody in acute sera than in chronic sera.

All the chronic sera and the majority of the acute sera were also able to precipitate the M<sub>\*</sub> 38 and 32K antigens. Although the M<sub>\*</sub> 38 and 32K antigens were

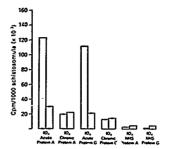

Fig. 5. The binding of antioodies from sera pooled from patients with acute and chronic schistosomias to the surface of schistosomials as measured with <sup>191</sup>-protein A and <sup>191</sup>-protein G. Bars marked 10<sub>2</sub> represent binding following treatment of schistosomial with sodium metaperiodate, NHS as normal human serum Each serum pool was used at a 1/10 dilution. Each bar is the average of duplicates

not precipitated by all the acute sera the statistical analysis revealed that there was no significant difference between the two groups. Indeed the consistency of precipitation of the M, 38 and 32K antigens is striking both by antibodies from the chronically infected patients included in the present study and from infected individuals in endemic areas of St Lucia (Simpson et al. 1986) and Brazil (Dissous et al. 1984) It is clear that the recognition of these two antigens contrasts that of the majority of antigenic polypeptides generated by the cell-free translation of mRNA where the recognition of individual proteins varies greatly between sera (Butterworth et al 1985; Simpson et al 1986, Newport et al 1988). Indeed, in this study, the immunoprecipitation of the M, 20K antigen as well as minor antigens of M, 40-100K were inconsistently precipitated by the individual sera

The chemical nature and life-cycle stage crossreactivity of the epitopes on the  $M_r > 200$ , 38 and 32K antigens were examined using separate serum pools constructed from the acute and chronic sera. It was thus demonstrated that the  $M_r > 200$ K antigen was recognized via carbohydrate epitopes which could be absorbed with an egg homogenate. In contrast, antibody to the M. 38 and 32K antigens was found to be against polypeptide epitopes that could be absorbed with an adult worm homogenate In the case of the acute serum pool, but not the chronic serum pool, there was also an apparent cross-reaction of epitopes recognized on the  $M_r$  38 and 32K antigens with the egg. Thus there may be low levels of these antigens present in the egg which were sufficient to absorb the anti-M, 38 and 32k

antibody from the acute serum pool but not from the chronic serum pool. It is possible, however, that the apparent absorption is due to proteolytic activity associated with the egg homogenate which degrades the lower level of antibody to the M, 38 and 32K antigens in the acute serum pool but is not sufficient to Jetectably reduce the higher levels of antibodies against other antigens. The reduction in absorption as a result of digestion with proteinase K and boiling is consistent with this hypothesis.

The principal findings from the immunoprecipitation experiments are the following. (1) There are different levels of IgG to the  $M_* > 200$ K antigen in the sera of the acute and chronic patients examined. (2) The epitopes recognized on the  $M_e > 200 \text{K}$ antigen are dependent on carbohydrate moieties that are cross-reactive with the schistosome egg. (3) There are no significantly different levels of anti-M. 38 and 32K antibody in the sera of the acute and chronic patients although the level of antibodies to these antigens is more variable in the acute sera and. as a result, they are found at a lower level in the acute pool. (4) The epitopes on the 38 and 32K antigens recognized by human sera are polypeptide and are strongly cross-reactive with the adult worm but weakly, if at all, with the egg. These findings are consistent with egg-cross-reactive anti-carbohydrate antibody making a significantly greater contribution to anti-schistosomulum surface antibody in the sera of acute patients than in the sera of chronic patients. This was indeed demonstrated by surface-binding experiments using sera pooled from the two patient types These demonstrated that pre-absorption of the sera with egg homogenate or pre-treatment of the schistosomulum surface with periodate both greatly reduced the binding of the acute serum pool but did not alter the binding of the chronic serum pool

These experiments demonstrate, that the correlations between human antibody levels to carbohydrate epitopes extracted from the schistosomulum and the egg as well as between antibody levels to noncarbohydrate epitopes extracted from the schistosomulum and the adult worm (Dunne et al 1988) can be accounted for by the recognition of crossreacting epitopes, and that at least some of the epitopes in question are exposed on the schistosomulum surface and establish the polypeptide nature of epitopes previously defined as 'noncarbohydrate' (Omer Ali et al. 1986, 1988; Dunne et al 1988) The findings are also consistent with the observation of Dunne and his colleagues that antiegg and anti-carbohydrate IgG both decline with age and thas, by inference, with longevity of infection They are also in agreement with the work of Gazzinelli and colleagues (Gazzinelli et al. 1985) who demonstrated higher levels of anti-egg antibody in acute than in chronic schistosomiasis patients in Brazil

A strong IgG response to schistosomulum surface

carbohydrate epitopes, including those expressed on the M<sub>t</sub> > 200K antigen have been detected in mice 12–15 weeks after infection (Omer Ali et al. 1986). Additionally, anti-poly peptide antibodies specific for the M<sub>t</sub> 38 and 32K antigens have been found both in infected mice and mice vaccinated with highly irradiated cercariae (Omer Ali et al. 1989). Thus there are strong similarities between the anti-schistosomulum surface antibody responses in man and the mouse model.

Murine monoclonal antibodies specific for carbohydrate epitopes on the  $M_* > 200$ , 38 and 17K antigens as well as a monoclonal antibody against a non-carbohydrate epitope on the M. 32K antigen have all been found to passively transfer resistance (Omer Ali et al. 1988) Thus it is possible that the human antibodies described in this paper may mediate immune killing in man. However, resistance to reinfection develops slowly after initial infection (Butterworth & Hagan, 1987) and it is reasonable to postulate that persistent rather than transient early responses are more likely to contribute to protective immunity in man Based on the findings in the present study, using a small number of sera, the antipolypeptide antibodies directed against the M, 38 and 32K antigens rather than the anti-carbohydrate antibodies directed against the  $M_{\star} > 200 \text{K}$  antigen are more likely to contribute to protective immunity in man. Nevertheless, the finding that these antigens are also recognized by acute patients is consistent with the hypothesis that potentially protective responses are blocked early in infection (possibly by anti-carbohydrate antibodies) as suggested by Butterworth and colleagues (see Butterworth & Hagan. 1987) It is also possible that there are differences in antibody isotype or affinity in the anti-M, 38 and 32K IgG response, during the course of infection, both of which have not been measured in the present

19 ABSTRACT (Continue on reverse if necessary	and identify by block n	umber)			
125 I - Schistosoma mansoni schist	cosomulum surfac	e antigens w	ere immunop	recipitated	with human
antibodies from individual Egypohanically infected with S. ma	otian patients d	lagnosed as	being either	r acutely o	r Ida amasa
bodies in their sara capable of	immunoprecipit	ating the ma	ior M >200	38 and 32	igu anti- K antidens
However, the immunoprecipitation	n of the M >20	OK antigen w	as found to	constitute	a signi-
figantly greater proportion of	the total preci	pitate achie	ved with act	ute sera th	an with
chronic sera. The Mr 38 and 32	X antigens were	more variab	ly precipita	ated by the	acute sera
than the chronic sera but the					
constituted was not found to be Immunoprecipitation with pooled	significantly Lantibodies abs	allierent be orbed with e	tween the ti	WO SEUS OI L WORM homo	sera, senster
which had been treated to remove	e either carboh	vdrate or po	lypeptide en	nitones dem	onstrated
that the M >200K antigen was tantibody amongst the antigens of	he principal ta	rget of egg-	cross-react:	ve anti-ca	rbohydrate

19. precipitated by antibodies to protease-sensitive and periodate-insensitive polypeptide epitopes. These results are consistent with egg-cross-reactive anti-carbohydrate IgG antibody making a greater contribution to schistosomulum surface recognition in acute infection than in chronic infection. Indeed the presence of a higher level of egg-cross-reactive and anti-carbohydrate antibody directed against schistosomulum surface epitopes in an acute serum pool than in a chronic serum pool was confirmed by measurement of antibody binding to whole schistosomula.
